- Recall that convergent and discriminant evidence reflects the degree to which test scores have the correct pattern of associations with other variables
- The conceptual foundation of a construct includes the connections between the construct and a variety of other psychological constructs
- The interconnections between a construct and other related constructs are known collectively as a **nomological network**

Nomological Networks: Example

References

- Baumeister and Leary (1995) introduced the construct "need to belong"
- They defined this as "the drive to form and maintain at least a minimum quantity of lasting, positive, and significant interpersonal relationships"
- Leary et al. (2006) theorised about the nomological network surrounding this construct and noted that:
 - the need to belong is similar to constructs such as the *need for affiliation*, the *need for intimacy*, *sociability*, and *extraversion*, but
 - unrelated to *conscientiousness*, *openness to experience*, and *self-esteem*

References

- Leary et al. (2006) proposed the following nomological network for the "need to belong" construct

Table: Nomological network for the construct "need to belong".

<i>Positive</i>	<i>Negative</i>	<i>Non-correlated</i>
Need for affiliation Sociability Extraversion	Social isolation	Conscientiousness Openness to experience Self-esteem

- A critical part of the validation process is estimating the degree to which test scores actually show the predicted pattern of associations

References

- There are cases where particular correlations between test scores and certain variables are "make-or-break"
- Consider the correlation between Scholastic Achievement Test (SAT) scores and first-year university marks
- The SAT is a standardized test designed to help universities select students
- It is very similar to an intelligence test, although it is somewhat more focussed on crystallised intelligence (e.g., vocabulary)
- For the SAT to be interpreted as a valid indicator of university performance, it must actually correlate with university marks

References

- Empirical research has yielded a correlation of .55 between SAT scores and first year university grades
- Another term for this particular focussed association is predictive validity—a type of criterion validity discussed in last week’s lecture
- A more general term is **validity coefficient**
- If research reveals that a test’s validity coefficients are generally large, then we have more confidence in using the test for its intended purpose

References

- The SAT and university grade correlation has been estimated based on 110,000 students from more than 25 universities
- Ideally, test users like to see validity coefficients that are generalizable to a broad array of people and circumstances
- Validity generalization is a process of evaluating a test's validity coefficients across a large set of studies

- In practice, many measures rely upon a small number of validity studies which include fewer than 400 participants
- Thus, in a lot of cases, it is an assumption that the test scores would be valid in a scenario different to that where it was tested
- For example, a measure of leadership may be useful for senior managers in banking, but it might not be useful for managers in the construction industry
- Perhaps different factors define leadership success in the construction industry, in comparison to the banking industry
- Validity generalization studies are intended to evaluate the predictive utility of a test's scores across a range of settings, times, situations, etc

References

- The textbook mentions the example of 25 studies which examined the association between conscientiousness and job performance
- Different results might be expected to be revealed, because they are based on different types of jobs
 - accountants, lecturers, sales people
- But some of the variance in the validity coefficients may be due to the manner in which job performance was measured
 - in some cases, job performance may be measured by amount of revenue generation
 - in another case, it might be measured based on peer and/or manager ratings

References

- The nomological network surrounding a construct does not always focus on a small number of pertinent criterion variables
- Sometimes a construct's nomological network incorporates a wide variety of other constructs, with differing levels of association with the main construct
- In such cases, researchers must compute the correlations between the test of interest and measures of many criterion variables
- They will then "eyeball" the correlations
- A subjective judgement is then made about the degree to which the pattern of coefficients matches that expected

- The Perfectionism Inventory (PI; Hill et al., 2004) was designed to measure eight facets of perfectionism (e.g., concern over mistakes, organization, planfulness)
- The authors administered their inventory, in addition to:
 - Multidimensional Perfectionism Scale
 - Multidimensional Perfectionism Scale
 - Fear of Negative Evaluation Scale
 - Brief Symptom Inventory (Depression, Anxiety, OCD)
 - Obsessive Compulsive Inventory
 - Marlowe-Crowne Social Desirability Scale
- Thus, they could evaluate convergent and divergent validity based on the pattern of correlations

Example: Perfectionism

Correlations Between Perfectionism Inventory Scales and Related Measures

Scale	CM	HS	NA	OR	PP	PL	RU	SE	CP	SEP	PL-C
Perfectionism: MPS-F ^a											
Concern Over Mistakes	.82	.43	.58	.18	.38	.30	.70	.52	.47	.78	.72

- Cronbach and Meehl described the concept of construct validity
- However, they did not fully describe a method to test construct validity
- Campbell and Fiske developed the logic of the multitrait-multimethod matrix as a statistical extension of Cronbach and Meehl's work
- The main problem the MTMM tries to overcome is the fact that a correlation between two scores may conflate two sources of variance:
 - **trait variance** (the good stuff)
 - **method variance** (the bad stuff)

- Researchers who use the MTMM approach to validate the interpretations of test scores must administer their inventory using different methods
 - at least three, in practice
- Essentially, the MTMM approach is based on the notion that we "hope" to see larger correlations between scores based on the same traits (irrespective of method of measurement), in comparison to correlations between scores based simply on the same method

- That is, large correlations between different traits using the same measurement method are not interesting theoretically
- It suggests that the correlations are simply due a response style (i.e., method variance)
- We want a lot shared trait variance, particularly identical traits measured using different methods

- For example, consider a measure of *social skill* that we may hope to validate
- We could administer the questionnaire in addition to other measures such as a measure of *impulsivity*, *conscientiousness*, and *emotional stability*
- Theoretically, we would expect some "small-ish" correlations between social skill and these other three measures
- This would be the **multitrait** component of the study

- In addition to collecting data via the *self-report method*, we could also use *acquaintance reports*
- That is, each person who completed the self-report questionnaires would have someone that knows them well to complete the same questionnaires phrased in the third person
- Also, the four traits (social skill, impulsivity, conscientiousness, emotional stability) could also be measured using an *interview based technique*
- Thus, there would be three methods of measurement: self-report, rater-report, and interview—the **multimethod** component of the study

The most stringent test in a MTMM analysis is to determine whether the monotrait-heteromethod correlations are "meaningfully" larger than the heterotrait-monomethod correlations

With respect to social skill, the mean "monotrait-heteromethod" correlation is equal to $.32$ $(.40 + .34 + .23) / 3$

Methods	Traits	Self-Report				Acquaintance Report				Acquaintance Report			
		Social Skill	Impulsivity	Conscientiousness	Emotional Stability	Social Skill	Impulsivity	Conscientiousness	Emotional Stability	Social Skill	Impulsivity	Conscientiousness	Emotional Stability

- Is the difference between **.32** and **.22** larger enough to merit a favourable evaluation of the social skill measure?
- That is one of the limitations associated with this approach
- There are no clear guidelines to evaluate the differences in the mean correlations
- At the very least, the monotrait-heteromethod correlations need to be larger than the heterotrait-monomethod correlations
- The lack of guidelines is probably one of the main reasons why MTMM studies are rare
- The other reason would be that they are labour intensive to conduct

- The methods described thus far are rather imprecise and subjective approaches to evaluating a pattern of convergent and discriminant correlations
- Westen and Rosenthal (2003) outlined a more precise and objective quantitative procedure called *quantifying construct validity* (QCV)
- Essentially, this procedure requires researchers to predict the magnitude of the correlation between their measure of interest and their selected criteria
- Then, the correlations between their measure of interest and these selected criteria are estimated
- Finally, the correlation between the predicted and estimated correlations is estimated

- Furr et al. (2004) examined the construct validity associated with a new measure of social motivation—a person's general desire to make positive impressions on other people
- The researchers had a group of five experts predict what the correlation would be between the measure of social motivation and 12 other self-report measures of personality like attributes (e.g., self-efficacy, agreeableness, need to belong)
- They then took the average of the estimates
- Next, they got people to respond to the questionnaires and estimated the empirical correlations

- The Pearson correlation between the "Predicted Correlations" and the "Actual Correlations" is equal to .79, a large positive correlation
- However, at this point in time, there are no clear guidelines regarding how large the correlation should be to be interpreted as providing evidence of adequate validity
- All we can say is that higher correlations offer greater evidence of validity
- The correlation of .79 would seem to indicate a high degree of convergent and discriminant validity

- The QCV approach has several advantages:
 - 1 It forces researchers to consider carefully the expected pattern of convergent and discriminant associations that would make theoretical sense
 - 2 It forces researchers to make explicit quantitative predictions about the pattern of associations
 - 3 It provides a single value reflecting the overall "goodness-of-fit" between the predicted and actual associations

- However, the approach is not without its limitations
- A low correlation between the predicted and actual associations does not necessarily reflect poor validity—the predicted associations may simply be a poor reflection of a construct’s nomological network
- Conversely, a high correlation between predicted and actual associations does not necessarily reflect good validity—it is possible to obtain a relatively large correlation when the predicted and actual associations do not closely match
- Some care is therefore required in interpreting the results of a QCV analysis

- Recall from our week 4 lecture that one factor affecting the correlation between measures of two constructs is the "true" association between those constructs
- If two constructs are strongly associated with each other, then measures of those constructs will likely be highly correlated with each other
- Conversely, if two constructs are unrelated to each other, then measures of those constructs will probably be weakly correlated with each other
- We tend to interpret correlations between measured variables as approximations of the true associations between the constructs we are interested in

References

- Recall from our week 4 lecture that the correlation between measures of two constructs is not only affected by the true association between those constructs
- It is also affected by measurement error
- Hence, the correlation between two measures is a function of the true correlation and the reliabilities of the two tests:

$$r_{x_o y_o} = r_{x_t y_t} \sqrt{R_{xx} R_{yy}} \quad (21)$$

- That is, measurement error reduces—or "attenuates"—the correlation between measures
- Measurement error therefore affects validity coefficients, just like any other correlation

- Researchers are generally satisfied if a test's reliability is above .70 or .80
- If a test's or a criterion's reliability is much lower than .70, then we should have concerns about its effect on a validity coefficient
- In this case there are two options:
 - 1 disregard—or reduce the weight given to—a validity coefficient based on poor reliability
 - 2 adjust the validity coefficient to account for measurement error

- As discussed in our week 4 lecture—and week 5 lab—correlation coefficients can be "disattenuated" for imperfect reliability using the *correction for attenuation* formula:

$$r_{x_t y_t} = \frac{r_{x_o y_o}}{\sqrt{R_{xx} R_{yy}}} \quad (22)$$

- This adjusts a validity correlation by assuming that both variables were measured without any measurement error

- There are at least three factors that affect the size of validity coefficients:
 - 1 True associations between constructs
 - 2 Measurement error and reliability
 - 3 Restricted range

- The amount of variability in one or both distributions of scores can affect the correlation between the two sets of scores
- Specifically, a correlation between two variables can be reduced if the range of scores in one or both variables is artificially limited or restricted

- The textbook gives the example of the correlation between SAT and GPA scores to illustrate restricted range
- Imagine a scenario where two students achieve a Grade Point Average of 4.0 (remember GPA scores vary between 0 and 4)
- As an A grade indicates an 80 or higher, it is possible for someone with an average of 81 to have a GPA of 4.0 and another person with an average of 91 to have a GPA of 4.0
- If we were to use GPA as the dependent variable, it would constrain the amount of variance that could be used in a correlation

- Range restriction can be difficult to diagnose
- If the range of obtained scores is dramatically different from the range of possible scores, then there might be a range restriction issue
- If the range of obtained scores falls to one "side" of the distribution of possible scores, then there might be serious concerns about range restrictions
- In the example, the impact is relatively small (from $r = .61$ to $r = .58$), but you should know that the effects can be much more pronounced
- There are no easy tricks for detecting range restriction, but it is a problem that you need to be aware of
